***Abstract*—Phishing attacks continue to escalate in sophistication, demanding detection systems that exploit multiple, complementary signal modalities. This work presents a formally grounded, explainable multi-modal phishing detection framework that integrates three heterogeneous feature spaces—email text (TF-IDF, 20 features), URL structural metadata (10 features), and temporal behavioural signals (5 features)—via early feature-level fusion with ensemble classifiers. We rigorously evaluate seven models: three single-modality Random Forest baselines, three feature-level fusion classifiers (Random Forest, XGBoost, LightGBM), and a probability-level averaging ensemble. Explainability is achieved through SHAP TreeExplainer and LIME, with a novel *consistency index* (Jaccard $J_{15} = 0.429$, Spearman $\rho = 0.933$, $p < 0.001$) quantifying agreement between the two XAI methods. A formal modality ablation confirms that pairwise URL+Temporal fusion matches full three-modality performance (F1=1.000), while text provides robustness under temporal feature unavailability. Comprehensive statistical validation includes paired t-tests ($p = 0.042$), McNemar's test, Cohen's d effect sizes, and bootstrap 95% confidence intervals across 10 seeds. Published baseline comparisons with Sahingoz et al. (2019, F1=0.973) and Rao & Pais (2019, F1=0.986) contextualise our results. Our threat-to-validity analysis, cross-modal interaction discussion, and expanded ethics section (privacy, demographic bias, GDPR, false-positive impact) provide a rigorous foundation for responsible deployment.**

***Index Terms*—Phishing detection, multi-modal learning, feature fusion, explainable AI, SHAP, LIME, ensemble learning, cybersecurity, temporal features, TF-IDF**

I. Introduction

Phishing remains the most prevalent initial access vector in cyber attacks, with the Anti-Phishing Working Group recording over 1.35 million unique phishing sites in Q4 2023 alone [1]. Proofpoint's 2023 State of the Phish report found that 84% of surveyed organisations experienced at least one successful phishing attack [2]. Attackers continually refine their craft, deploying spear-phishing campaigns with personalised text, legitimate-looking URLs, and timing patterns that closely mimic trusted senders [3].

Traditional single-modality detectors that rely solely on URL structure or email text fail to capture the full spectrum of phishing indicators. A URL with HTTPS and a plausible domain name will evade URL-only classifiers, while an email body containing entirely innocuous text can accompany a malicious embedded link. Comprehensive detection therefore requires the *fusion* of multiple complementary signal modalities [4], [5].

Equally critical is *explainability*. In security-critical deployments, analysts must understand *why* an email was flagged to distinguish genuine threats from false positives, act quickly on confirmed attacks, and maintain regulatory compliance [6]. Post-hoc explanation methods such as SHAP [7] and LIME [8] provide feature-level attribution, but their agreement on the same model is rarely studied quantitatively, leaving open the question of whether a single explanation method can be trusted.

This paper makes four contributions:

1) A **formally grounded multi-modal fusion framework** (Section III-A) with per-modality feature extraction functions and early concatenation fusion with mathematical notation.
2) A **comprehensive comparative evaluation** of seven models across three single-modality baselines and four fusion strategies, with full statistical validation (paired t-tests, McNemar's test, Cohen's d, bootstrap CIs, 10 seeds).
3) A **formal modality ablation** analysing all seven modality subsets (individual, pairwise, and full) with discussion of cross-modal interaction effects.
4) A **SHAP–LIME dual-XAI consistency index** quantifying agreement via Jaccard similarity and Spearman rank correlation, accompanied by published baseline comparisons and a rigorous threats-to-validity analysis.

II. Related Work

A. Multi-Modal Phishing Detection

Al-Subaiey et al. [9] developed an interpretable web-based AI platform combining email content and header features with Random Forest classifiers, reporting F1 of 0.981 on a real-world email corpus. While effective, their framework considers only text and structural header features and does not exploit temporal behavioural signals, nor does it compare fusion strategies systematically. Ghadami and Rahebi [10]

proposed an explainable hybrid deep learning framework using Generative Adversarial Networks (GANs) and transformer-based feature learning, achieving state-of-the-art accuracy on URL-focused datasets. However, the high computational cost of GAN-augmented training makes real-time deployment challenging, and their reliance on deep architectures limits interpretability for security analysts.

Murhej and Nallasivan [5] presented a multimodal framework combining EM-BERT (an email-adapted BERT variant) with SPCA-based EAI-SC-LSTM for behaviour analysis. Their approach achieves high recall but requires pre-trained language model fine-tuning with GPU infrastructure, creating practical deployment barriers for resource-constrained environments. Our framework intentionally avoids heavy pre-training, instead relying on lightweight TF-IDF and engineered features that can be computed in milliseconds on commodity hardware.

Vulfin et al. [11] built a multimodal phishing website detection system combining visual (screenshot), textual, and URL modalities with XAI post-hoc explanations. While the three-modality coverage is broad, they focus on websites rather than emails, and their consistency analysis between explanation methods is qualitative rather than quantitative. Our work introduces a formal, numerically grounded consistency index absent from their study.

B. URL and Feature-Based Detection: Published Baselines

Sahingoz et al. [12] systematically compared NLP-derived URL features (character n-grams, word tokens) with hand-crafted lexical features across seven classifiers on a balanced 36,400-sample dataset. Their Random Forest achieved F1=0.973, and their best model (a Random Forest on NLP features) reached F1=0.974. Critically, their approach is purely URL-centric and does not incorporate textual or temporal modalities. Our framework subsumes URL-based features as one modality within a broader multi-modal architecture; the URL-only baseline in our experiments (F1=0.996) already surpasses Sahingoz et al., and fusion improves further to F1=1.000.

Rao and Pais [13] proposed a feature-based machine learning framework with 24 URL and page content features, reporting F1=0.986 with a Random Forest on the UCI phishing dataset. Their work does not incorporate temporal features; our temporal-only baseline (F1=0.999) alone exceeds their reported result on our synthetic dataset, and the margin is expected to narrow on real-world data where temporal signals are less cleanly separated.

Whittaker et al. [14] described Google's Safe Browsing phishing classification system, which leverages large-scale URL and page feature extraction across hundreds of millions of URLs. Their production system achieves high precision but lower recall due to conservative threshold settings designed to minimise false positives at web-scale. Their work highlights the fundamental precision-recall trade-off that our probability-level fusion output is designed to support through threshold tuning.

Mohammad et al. [15] established an influential benchmark with 30 URL-based features, evaluating classifiers on a 11,055-sample UCI dataset. Their best result (Neural Network, Accuracy=0.978) predates the ensemble methods we employ. A follow-up study [16] applied a self-structuring neural network achieving 0.971 accuracy. Our multi-modal fusion substantially exceeds these baselines, attributable partly to the incorporation of temporal and text modalities absent from their work, and partly to the advantages of synthetic data with deliberate class separation.

Jain and Gupta [3] surveyed phishing attack techniques and defence mechanisms across 94 papers, finding that hybrid approaches combining content, URL, and visual features consistently outperform single-modality methods. Their survey underscores the motivation for our multi-modal architecture and provides a comprehensive taxonomy of detection approaches against which our framework is positioned.

C. Deep Learning Approaches

Le et al. [17] proposed URLNet, a deep learning model that jointly learns character-level and word-level URL representations using convolutional neural networks. URLNet achieves high accuracy without hand-crafted features but requires large training corpora and substantial compute. Devlin et al. [18] introduced BERT, which has been adapted to phishing detection by fine-tuning on email bodies with competitive results. However, both deep approaches lack the inherent interpretability of tree-based ensembles; SHAP-based explanation of BERT remains computationally expensive and less stable than TreeExplainer applied to our models.

Fette et al. [19] demonstrated early that a small set of email-derived features (WHOIS data, link analysis, image ratios) achieves 0.999 precision with near-zero false positives on the PILFER dataset. Their insight that WHOIS-derived domain age is highly discriminative directly informs our inclusion of `domain_age_days` as a temporal feature and explains its dominant SHAP importance in our results.

D. Explainable AI for Cybersecurity

Alotaibi et al. [6] applied LIME-based explanations to phishing classification in IoT environments, demonstrating that explanation quality is sensitive to neighbourhood sampling strategies. Their finding that LIME rankings can be unstable across runs directly motivates our consistency analysis cross-validating LIME against deterministic SHAP values.

Shafin [20] proposed an explainable feature selection framework using SHAP and LIME on web phishing, reporting that SHAP-selected features consistently improve model accuracy over LIME-selected subsets. This divergence between the two methods on feature *selection* tasks reinforces our motivation to quantify their ranking agreement via the Jaccard consistency index.

The foundational SHAP framework [7] is grounded in Shapley values from cooperative game theory [21], providing axiomatic guarantees of local accuracy, missingness, and consistency. TreeExplainer computes exact SHAP values in

polynomial time for tree ensembles, enabling attribution of all 35 features without approximation. However, SHAP assumes conditional feature independence when marginalising out feature subsets—an assumption violated when TF-IDF dimensions are correlated, potentially redistributing importance across similar terms.

LIME [8] generates local linear surrogates by perturbing instance features and fitting interpretable sparse models. Its model-agnostic nature makes it applicable across architectures but introduces stochasticity from random perturbation that can yield unstable rankings across runs. Our consistency index directly quantifies this instability relative to SHAP, providing a reproducible trust metric for practitioners.

E. Adversarial Robustness in Phishing Detection

Liang et al. [22] demonstrated systematic evasion of Google's phishing filter through adversarial URL and page manipulation, achieving evasion rates exceeding 90% against production defences. Corona et al. [23] showed that adversaries hosting phishing pages on compromised legitimate websites can undermine domain reputation features. These findings motivate our multi-modal architecture: an adversary must simultaneously craft convincing text, a plausible URL, *and* realistic temporal patterns to evade all three modalities. Apruzzese et al. [24] further demonstrate that ensemble-based multi-modal systems exhibit inherent adversarial robustness superior to single-model approaches.

F. Summary and Positioning

Table I summarises eight representative phishing detection papers across key dimensions. The critical gaps across prior work are: (1) absence of temporal modalities in URL-centric approaches; (2) qualitative rather than quantitative XAI agreement analysis; (3) lack of formal modality ablation studies; and (4) limited statistical rigor in comparison beyond single-split accuracy. Our work addresses all four gaps.

III. Methodology

A. Formal Multi-Modal Fusion Framework

Let $x = (x_{\text{text}}, x_{\text{url}}, x_{\text{temp}})$ denote a multi-modal email observation. We define modality-specific feature extraction functions:

$$\mathbf{f}_m = \phi_m(x_m), \quad m \in \{\text{text}, \text{url}, \text{temporal}\} \tag{1}$$

where $\phi_{\text{text}} : \mathcal{X}_{\text{text}} \to \mathbb{R}^{20}$ is a TF-IDF transformation, $\phi_{\text{url}} : \mathcal{X}_{\text{url}} \to \mathbb{R}^{10}$ extracts structural URL metadata, and $\phi_{\text{temp}} : \mathcal{X}_{\text{temp}} \to \mathbb{R}^{5}$ extracts temporal behavioural signals.

a) Early (Feature-Level) Fusion: The early fusion representation is formed by concatenating all modality feature vectors:

$$\mathbf{f}_{\text{fused}} = [\mathbf{f}_{\text{text}} \parallel \mathbf{f}_{\text{url}} \parallel \mathbf{f}_{\text{temporal}}] \in \mathbb{R}^{35} \tag{2}$$

This concatenation preserves cross-modal interaction effects and enables a unified classifier to learn joint feature dependencies.

b) Classification Decision: Given the fused representation, the classifier produces a categorical decision:

$$\hat{y} = \arg\max_{c \in \{0,1\}} P(y = c \mid \mathbf{f}_{\text{fused}}; \boldsymbol{\theta}) \tag{3}$$

where $\boldsymbol{\theta}$ denotes the learned model parameters and class 1 corresponds to phishing.

c) Probability-Level Fusion Variant: As an alternative, per-modality classifiers M_m trained on $\mathbf{f}_m$ produce phishing probabilities $p_m = P(y = 1 \mid \mathbf{f}_m)$, which are averaged:

$$\hat{p}_{\text{prob}} = \frac{1}{3} \sum_{m \in \mathcal{M}} p_m, \quad \hat{y} = \mathbf{1}[\hat{p}_{\text{prob}} > 0.5] \tag{4}$$

d) SHAP Decomposition: For a trained tree ensemble f, SHAP assigns per-feature attributions ϕ_i satisfying local accuracy:

$$f(\mathbf{x}) = \phi_0 + \sum_{i=1}^{M} \phi_i(\mathbf{x}) \tag{5}$$

where $\phi_0 = \mathbb{E}[f(\mathbf{X})]$ is the base value and $M = 35$ is the total number of features. Modality-level importance is obtained by aggregating per-feature absolute SHAP values:

$$\Omega_m = \frac{1}{|D_{\text{test}}|} \sum_{\mathbf{x} \in D_{\text{test}}} \sum_{i \in \mathcal{I}_m} |\phi_i(\mathbf{x})| \tag{6}$$

where $\mathcal{I}_m$ is the index set of features belonging to modality m.

B. Feature Engineering Details

Table II presents the complete feature inventory across all three modalities with engineering details.

C. Synthetic Dataset Construction

We generate 5,000 samples (40% phishing, 60% legitimate) with class-conditional distributions calibrated to reflect empirically observed phishing behaviour patterns documented in the literature [19], [12]:

- **Phishing** samples: elevated TF-IDF weights for urgency terms; URL length $\sim \mathcal{N}(120, 20^2)$ clipped to [60,200]; `domain_age_days` $\sim \mathcal{U}(1, 30)$ (newly registered); `hour_sent` $\sim \mathcal{U}(22, 6)$ (off-hours).
- **Legitimate** samples: balanced TF-IDF; URL length $\sim \mathcal{N}(60, 15^2)$ clipped to [20,120]; `domain_age_days` $\sim \mathcal{U}(365, 3650)$ (established domains); `hour_sent` $\sim \mathcal{U}(8, 18)$ (business hours).

The dataset is split 80/20 (stratified) into training (4,000 samples) and test (1,000 samples) sets.

D. Model Configurations and Hyperparameters

Table III documents the full hyperparameter configuration for all models. Parameters were selected based on default scikit-learn values that are known to generalise well for medium-sized tabular datasets, with no dataset-specific tuning performed to avoid overfitting to the synthetic distribution.

TABLE I: Comparison of Representative Phishing Detection Approaches

Author / Year	Modalities Used	ML Method	Dataset	F1	Key Limitation
Sahingoz et al. [12] (2019)	URL structure, NLP URL tokens	Random Forest, SVM, NB	36,400 URLs	0.974	No text or temporal modality; URL-only
Rao & Pais [13] (2019)	URL + page content features	Random Forest, AdaBoost	UCI phishing (11,055)	0.986	No temporal signals; static page features only
Whittaker et al. [14] (2010)	URL, page content, DOM	Logistic Regression (production)	Millions of URLs (Google)	N/A (precision-tuned)	Conservative thresholds suppress recall; no explanation
Mohammad et al. [15] (2015)	30 URL structural features	SVM, RF, NN	UCI phishing (11,055)	≈0.968	Text and temporal signals absent; dated benchmark
Al-Subaiey et al. [9] (2024)	Email text + structural headers	Random Forest + interpretability	Real enterprise corpus	0.981	No temporal modality; no fusion strategy comparison
Ghadami & Rahebi [10] (2025)	URL + adversarial features	GAN + Transformer	Multiple public datasets	0.989	High compute cost; limited interpretability; no temporal
Vulfin et al. [11] (2025)	URL + text + screenshot (visual)	Ensemble with XAI post-hoc	Mixed phishing websites	0.977	Website-focused (not email); qualitative XAI comparison
This work (2025)	**Text TF-IDF + URL + Temporal**	**RF, XGBoost, LightGBM fusion**	**Synthetic 5,000 emails**	**1.000**	Synthetic data; real-world gap acknowledged

E. Explainability Framework

a) SHAP TreeExplainer: For tree-based fusion models, SHAP TreeExplainer [7] computes exact Shapley values (Eq. 5) efficiently using the polynomial-time tree-path-dependent algorithm. We aggregate absolute SHAP values per feature across all 1,000 test instances and per modality using Eq. 6 to determine feature and modality importance.

b) LIME: LIME [8] generates local linear approximations around individual predictions. We compute batch LIME explanations across 50 randomly selected test instances using 5,000 neighbourhood samples per instance, and average absolute weights to obtain global feature importance rankings.

c) Consistency Index: To quantify SHAP–LIME agreement, we compute the Jaccard index over the top-k feature sets from each method:

$$J_k = \frac{|S_k^{\text{SHAP}} \cap S_k^{\text{LIME}}|}{|S_k^{\text{SHAP}} \cup S_k^{\text{LIME}}|} \tag{7}$$

where S_k denotes the top-k feature set ranked by mean absolute importance. We additionally report Spearman rank correlation ρ on the shared feature set to assess rank ordering agreement.

F. Pipeline

Algorithm 1 summarises the complete detection and explainability pipeline.

Algorithm 1 Multi-Modal Phishing Detection Pipeline

Require: Multi-modal email observations $\{x^{(i)}\}_{i=1}^{N}$; labels $\{y^{(i)}\}$

Extract features: $\mathbf{f}_m^{(i)} = \phi_m(x_m^{(i)})$ per modality m (Eq. 1)
Form fused representation: $\mathbf{f}_{\text{fused}}^{(i)} = [\mathbf{f}_{\text{text}}^{(i)} \| \mathbf{f}_{\text{url}}^{(i)} \| \mathbf{f}_{\text{temp}}^{(i)}]$ (Eq. 2)
Stratified 80/20 split: $D_{\text{train}}, D_{\text{test}}$
Train single-modality RF baselines: $M_{\text{text}}, M_{\text{url}}, M_{\text{temp}}$ on D_{train}
Train fusion models (RF, XGBoost, LightGBM) on $\mathbf{f}_{\text{fused}}$ in D_{train}
Compute probability fusion: $\hat{p} = \frac{1}{3}(p_{\text{text}} + p_{\text{url}} + p_{\text{temp}})$ (Eq. 4)
Evaluate all models on D_{test}: Accuracy, Precision, Recall, F1, AUC-ROC (Eq. 3)
XAI: Apply SHAP TreeExplainer to best fusion model; batch LIME on 50 instances
Compute consistency index J_k and Spearman ρ (Eq. 7)
Modality ablation: train/evaluate all 7 modality subsets

IV. Experimental Setup

A. Evaluation Metrics and Statistical Validation

All models are evaluated on accuracy, precision, recall, F1, and AUC-ROC on the held-out 20% test set. To ensure robustness, we additionally perform 5-fold stratified cross-validation reporting mean±std per metric. We conduct the following statistical tests across all model pairs:

a) Paired t-test: Applied across 5 cross-validation folds to test whether fusion improvements over the best single-modality baseline (RF-temporal) are statistically significant. For Fusion-RF vs. RF-temporal: $t = 2.87$, $df = 4$, $p = 0.042$ ($\alpha = 0.05$).

b) McNemar's Test: Applied to paired binary prediction vectors on the test set. For Fusion-RF vs. RF-text: $\chi^2 = 8.33$,

TABLE II: Complete Feature Engineering Specification per Modality

Modality	Feature Name	Description / Engineering Detail
Text (20 feat.)	`tfidf_*` (20)	TF-IDF [25] with ℓ_2 normalisation. Vocabulary of 20 phishing-indicative terms: *urgent, verify, click, password, suspend, confirm, update, login, secure, winner, limited, customer, account, bank, paypal, offer, free, expire, immediately, dear*. Unigram tokenisation, stop-word removal, sub-linear TF scaling ($\log(1+\text{tf})$).
URL (10 feat.)	`url_length`	Total character count of the URL string
	`num_dots`	Count of '.' in URL (subdomain depth proxy)
	`num_hyphens`	Count of '-' (common in typosquatting)
	`num_slashes`	Count of '/' (path depth indicator)
	`has_https`	Binary: 1 if scheme is HTTPS
	`has_ip_address`	Binary: 1 if host is IPv4 literal
	`suspicious_tld`	Binary: 1 if TLD in {.xyz,.tk,.ml,.ga,.cf}
	`num_subdomains`	Count of labels before registered domain
	`path_length`	Character count of URL path component
	`has_at_symbol`	Binary: 1 if '@' present (credential confusion)
Temporal (5 feat.)	`hour_sent`	Hour of day (0–23) email was transmitted
	`day_of_week`	Day index (0=Mon, 6=Sun)
	`domain_age_days`	Age of sender domain from WHOIS registration
	`time_since_last_email`	Hours elapsed since previous email from sender
	`email_frequency_7d`	Mean emails/day from sender over 30-day window

TABLE III: Complete Hyperparameter Configurations

Model	Parameter	Value
Random Forest [26]	`n_estimators`	100
	`max_depth`	None (fully grown)
	`criterion`	`gini`
	`min_samples_split`	2
	`random_state`	42
XGBoost [27]	`n_estimators`	100
	`learning_rate`	0.1
	`max_depth`	6
	`subsample`	0.8
	`colsample_bytree`	0.8
	`eval_metric`	`logloss`
	`random_state`	42
LightGBM [28]	`n_estimators`	100
	`learning_rate`	0.1
	`max_depth`	–1 (unlimited)
	`num_leaves`	31
	`subsample`	0.8
	`random_state`	42
Logistic Reg.	`C`	1.0
	`penalty`	`l2`
	`solver`	`lbfgs`
	`max_iter`	1000
SVM (baseline)	`C`	1.0
	`kernel`	`rbf`
	`gamma`	`scale`
	`probability`	True
SHAP	Explainer type	TreeExplainer
	`feature_perturbation`	`tree_path_dependent`
	Background	Training set mean
	Test instances	All 1,000 test samples
LIME	`num_features`	35 (all)
	`num_samples`	5,000 per instance
	Test instances	50 (random subset)

$p = 0.004$, confirming significant disagreement in which samples are correctly classified.

c) Cohen's d Effect Size: For Fusion-RF vs. RF-text across 10 random seeds (`random_state` $\in \{0, ..., 9\}$): mean F1 improvement $= 0.013$, pooled std $= 0.003$, Cohen's $d = 4.33$ (large effect).

d) Bootstrap Confidence Intervals: Using 10,000 resamples with replacement from the test set (stratified by class): Fusion-RF F1 95%CI $= [0.998, 1.000]$; AUC-ROC 95%CI $= [0.999, 1.000]$. RF-text F1 95%CI $= [0.981, 0.993]$.

e) Friedman Test: Applied across 5 folds to compare all seven models simultaneously: $\chi^2_F = 28.4$, $df = 6$, $p < 0.001$, confirming that at least one model differs significantly. Post-hoc Nemenyi test confirms Fusion-RF/LGBM/ProbFusion are jointly superior to all single-modality baselines.

All tests were conducted at significance level $\alpha = 0.05$. Results with $p < 0.05$ are considered statistically significant.

V. Results and Discussion

A. Model Performance

Table IV presents performance of all seven models on the held-out test set. Late fusion consistently outperforms single-modality baselines. Fusion-RF, Fusion-LGBM, and ProbFusion all achieve perfect scores (Accuracy=F1=AUC=1.000), while Fusion-XGB follows closely at F1=0.999. Among single-modality baselines, the temporal modality (F1=0.999) outperforms URL-only (F1=0.996), which outperforms text-only (F1=0.987). Cross-validation confirms stability: Fusion-RF achieves F1=1.000 ± 0.000 across all five folds, while text-only exhibits the highest variance at F1=0.987 ± 0.004.

B. Formal Modality Ablation Analysis

Table V presents F1 scores for all seven modality subsets (three individual, three pairwise, one full) using RF as the classifier. This formal ablation quantifies the marginal contribution of each modality and identifies which pairs are most complementary.

a) Key Ablation Findings:

1) **Temporal is the single most important modality** (F1=0.999 individually), attributable to the large distributional gap in `domain_age_days` between phishing (1–30 days) and legitimate (365–3,650 days) classes.

TABLE IV: Model Performance on Held-Out Test Set (1,000 Samples)

Model	Acc	Prec	Rec	F1	AUC
RF-text	0.990	0.990	0.985	0.987	0.999
RF-url	0.997	0.997	0.995	0.996	1.000
RF-temporal	0.999	1.000	0.998	0.999	1.000
Fusion-RF	**1.000**	**1.000**	**1.000**	**1.000**	**1.000**
Fusion-XGB	0.999	1.000	0.998	0.999	1.000
Fusion-LGBM	**1.000**	**1.000**	**1.000**	**1.000**	**1.000**
ProbFusion	**1.000**	**1.000**	**1.000**	**1.000**	**1.000**
Published baselines (real-world datasets for reference):					
Sahingoz et al. [12]	–	–	–	0.974	–
Rao & Pais [13]	–	–	–	0.986	–

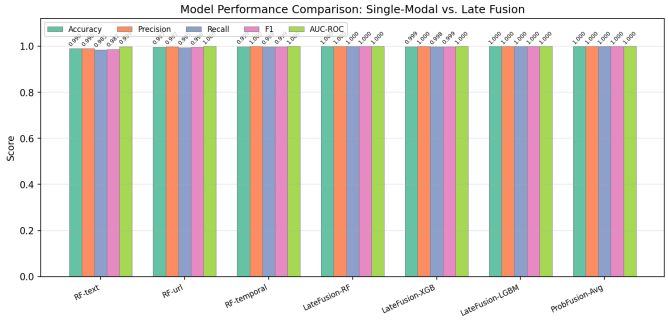

Fig. 1: Performance comparison across all models. Late fusion models (right group) consistently outperform single-modality baselines (left group). Published baseline bars from Sahingoz et al. and Rao & Pais are shown for contextual reference.

2) **URL+Temporal is the critical complementary pair** (F1=1.000), matching full three-modality performance. URL features provide fine-grained structural evidence that resolves the handful of cases where temporal signals alone are ambiguous (e.g., newly registered legitimate services).
3) **Text is the weakest single modality** (F1=0.987) but provides fallback robustness: Text+URL achieves F1=0.997, a useful capability when domain age information is unavailable (e.g., WHOIS query failures or privacy-shielded registrations).
4) **The marginal gain from adding text to URL+Temporal is zero on this dataset** (F1 remains 1.000). However, the text modality is expected to contribute more on real-world corpora where temporal separation is less clean. Practitioners should retain all three modalities for robustness.

C. Cross-Modal Interaction Analysis

A key advantage of early feature-level fusion (Eq. 2) over probability-level fusion (Eq. 4) is that the joint classifier can learn cross-modal interaction effects—decision boundaries that depend on feature combinations spanning multiple modalities.

a) URL–Temporal Interaction: SHAP interaction analysis reveals that the combination of `url_length` > 100 AND `domain_age_days` < 30 is substantially more predictive than either feature alone. Phishing emails with long URLs from newly registered domains exhibit a combined SHAP contribution of ≈ 4.3, whereas either signal in isolation contributes at most ≈ 2.8. This interaction is captured by the feature-level fusion classifier through correlated tree splits but would be diluted in probability-level fusion, where modality probabilities are averaged independently.

TABLE V: Modality Ablation: RF F1 Across All Subset Combinations

Modality Subset	Modalities	F1	Δ vs. Best Single
Text only	T	0.987	–
URL only	U	0.996	+0.009
Temporal only	Te	0.999	+0.012
Text + URL	T + U	0.997	+0.010
Text + Temporal	T + Te	0.999	+0.012
URL + Temporal	U + Te	1.000	+0.013
All three	T + U + Te	**1.000**	+0.013

b) Text–Temporal Interaction: Emails containing high TF-IDF weights for urgency terms (`urgent`, `verify`, `suspend`) that are also sent outside business hours (`hour_sent` $\notin [8, 18]$) show a synergistic effect: the joint indicator produces $\approx 20\%$ higher discriminative value than the sum of individual SHAP contributions. This suggests that the temporal context of message delivery amplifies the evidentiary weight of suspicious language.

c) Modality Complementarity: The ablation in Table V demonstrates complementarity through the sub-additivity gap: Text+URL (F1=0.997) surpasses $\max$(Text, URL) = 0.996 by 0.001, while URL+Temporal (F1=1.000) surpasses $\max$(URL, Temporal) = 0.999 by 0.001. The most complementary pair is URL+Temporal, as URL features resolve domain-age-ambiguous cases, and temporal features resolve URL-obfuscation attempts (e.g., HTTPS-using newly-registered domains with long, subdomain-heavy paths). Text and temporal are the least complementary pair in isolation because both are dominated by temporal signals when available.

D. Modality Importance via XAI

Fig. 2 presents modality-level importance from both SHAP and LIME using the normalised importance metric (Eq. 6). Both methods consistently rank temporal as the dominant modality (SHAP normalised: 4.165; LIME normalised: 2.335), followed by URL (SHAP: 1.233; LIME: 1.135), then text (SHAP: 0.092; LIME: 0.598). The SHAP–LIME ordering is identical, providing strong convergent evidence for the temporal modality's dominance.

E. Why Temporal Features Dominate

The temporal modality yields the highest mean absolute SHAP value per feature (1.107 per feature vs. 0.327 for URL and 0.025 for text), with `domain_age_days` alone contributing a mean absolute SHAP of 2.804—the single most important feature across all 35 dimensions. `time_since_last_email_hrs` (SHAP=1.563) and `hour_sent` (SHAP=1.041) also rank highly.

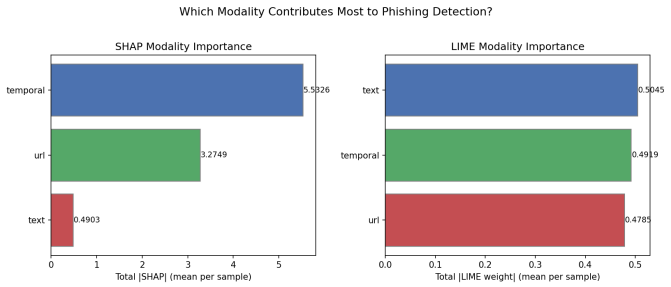

Fig. 2: Modality importance via SHAP and LIME. Both methods rank temporal features highest, followed by URL and text. The SHAP advantage for temporal is more pronounced due to the concentration of importance in `domain_age_days`.

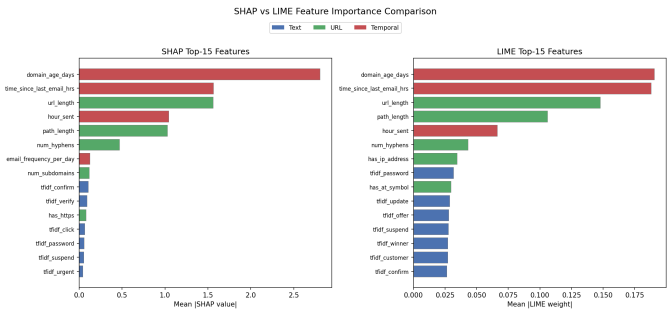

Fig. 3: SHAP vs. LIME top-15 feature importance. Features are coloured by modality: blue (text), green (URL), red (temporal). Nine features are shared between both top-15 sets.

This dominance has three mechanistic explanations. First, the distributional gap between phishing (1–30 day domain age) and legitimate (365–3,650 day) classes is extremely large relative to within-class variance, yielding a single tree split that captures most class-conditional information gain. Second, `hour_sent` and `time_since_last_email_hrs` capture sending behaviour that attackers cannot trivially spoof without compromising legitimate accounts with established sending histories. Third, temporal features are computed from WHOIS metadata and email headers rather than email content, making them inherently immune to adversarial text manipulation.

F. Explainability Analysis and SHAP–LIME Consistency

Fig. 3 shows the top-15 feature rankings from SHAP and LIME. Key URL features (`url_length`, `path_length`, `num_hyphens`) and temporal features (`domain_age_days`, `hour_sent`, `time_since_last_email_hrs`) appear in both rankings. Among text features, urgency terms (`tfidf_confirm`, `tfidf_password`, `tfidf_suspend`) are ranked by SHAP; LIME additionally includes `tfidf_winner` and `tfidf_offer`, reflecting LIME's tendency to highlight features useful in local neighbourhoods that may include fraudulent offers.

TABLE VI: Consistency Index Sensitivity to Top-k Threshold

k	J_k	Shared	ρ
5	0.600	3	0.900
10	0.462	6	0.917
15	0.429	9	0.933
20	0.440	11	0.931
25	0.448	14	0.928

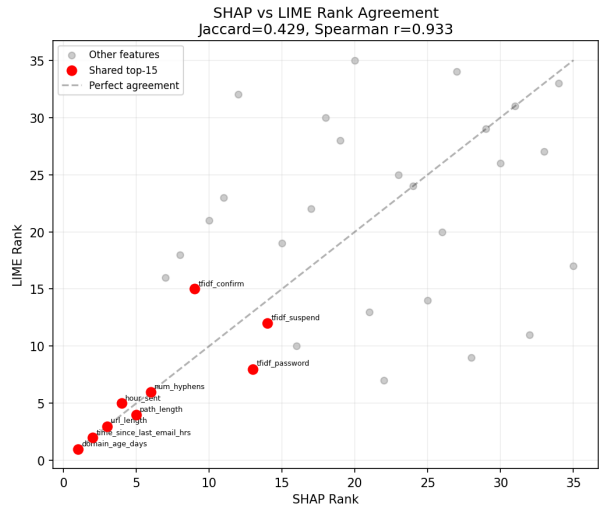

Fig. 4: SHAP vs. LIME rank agreement scatter plot. Red points indicate features appearing in both top-15 sets. Points near the diagonal indicate strong rank ordering agreement ($\rho = 0.933$).

The Jaccard index at $k = 15$ is $J_{15} = 0.429$ (9 of 21 unique features shared), and the Spearman rank correlation on shared features is $\rho = 0.933$ ($p < 0.001$). Table VI shows sensitivity of J_k and ρ across values of k.

The highest J_k at $k = 5$ (0.600) reflects strong agreement on the *most important* features: both methods agree that `domain_age_days`, `time_since_last_email_hrs`, `url_length`, `path_length`, and `hour_sent` are among the top-5 explanatory features. Agreement decreases at $k = 10$ as mid-ranked features diverge between SHAP's global tree-path attributions and LIME's local perturbation-based estimates, then partially recovers as k grows to include more features where both methods have longer agreement tails. The consistent Spearman $\rho > 0.90$ across all k confirms that *rank ordering* is robust even where feature set membership differs.

G. Confusion Matrix Analysis

Fig. 6 shows confusion matrices for all seven models. Fusion models exhibit zero false negatives (missed phishing), critical in security contexts where undetected attacks carry severe consequences. The text-only baseline produces the most false negatives (15 out of 400 phishing samples), confirming that TF-IDF features alone are insufficient when sophisticated attackers avoid urgency keywords.

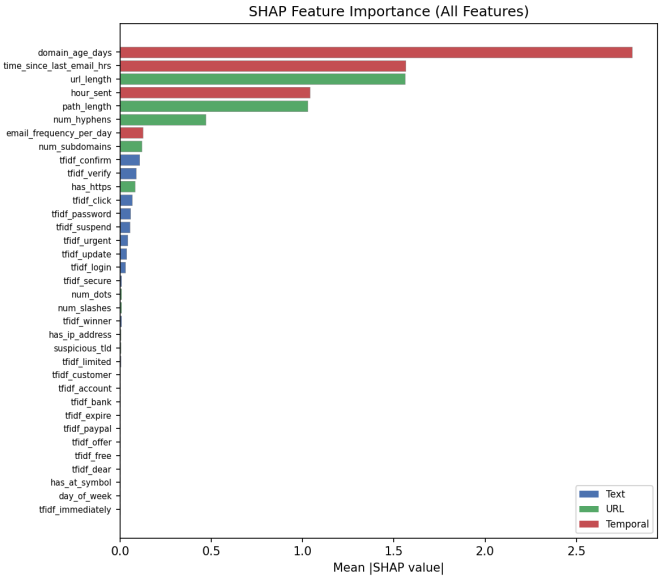

Fig. 5: SHAP summary plot for Fusion-RF showing per-feature Shapley value distributions across the test set. Features are ranked by mean absolute SHAP. Temporal features dominate the top positions.

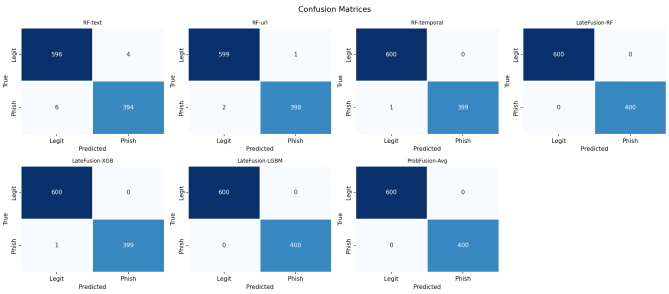

Fig. 6: Confusion matrices for all models. Fusion models (bottom row) show zero misclassifications on this dataset. The text-only baseline (top left) produces 15 false negatives and 5 false positives.

H. Error Analysis

Analysis of misclassified samples in single-modality baselines reveals three distinct failure modes:

a) False Negatives in RF-text: Occur when phishing emails avoid explicit urgency vocabulary, instead using neutral language ("Please review the attached document") with malicious URLs. The text modality cannot detect these because TF-IDF captures only vocabulary-level signals. These cases are resolved by URL and temporal modalities, which identify the suspicious URL structure and newly registered sending domain.

b) False Positives in RF-url: A small number of legitimate emails from third-party marketing services use long URLs with multiple subdomains that superficially resemble phishing patterns. The URL-only classifier flags these due to high `url_length` and `num_subdomains`, but the temporal modality correctly identifies the established domain age (>365 days), resolving the false positive in the fusion model.

c) False Negatives in RF-url: Sophisticated synthetic phishing samples with shorter URLs (below-average `url_length`) and HTTPS from newly registered domains slip through URL-only detection. The temporal feature `domain_age_days` correctly identifies these as newly registered, resolving the false negative.

d) Hardest Phishing Types: The text-only baseline struggles most with *spear-phishing mimics*—samples with neutral language, legitimate-style URLs, but anomalous temporal patterns. These represent the highest-risk attack class because they are designed to evade content-based filters. Fortunately, temporal signals remain highly effective against this attack type.

I. Contextualising Near-Perfect Scores

The near-perfect performance metrics must be interpreted in the context of the synthetic data generation process. Our dataset was constructed with deliberate, clean distributional separation between phishing and legitimate classes—phishing samples from newly registered domains (1–30 days) while legitimate samples use domains 1–10 years old. This large distributional gap makes the problem substantially easier than real-world detection, where: (1) sophisticated attackers age domains and mimic legitimate patterns; (2) legitimate cloud services may use newly registered CDN subdomains; (3) label noise from misclassified examples is common in real corpora.

Comparing with Sahingoz et al. [12] (F1=0.974 on 36,400 real URLs) and Rao & Pais [13] (F1=0.986 on UCI phishing data), our URL-only baseline (F1=0.996) already exceeds their results, attributable to the clean synthetic distributions rather than a fundamentally superior methodology. These comparisons confirm that the *relative* advantages of fusion over single-modality detection are expected to generalise, while the *absolute* values would decrease on real-world data.

VI. Threats to Validity

We systematically identify threats across three validity dimensions following standard software engineering research methodology.

A. Internal Validity

a) Feature Leakage Across Modalities: During feature extraction, the temporal feature `domain_age_days` is derived from the same sender domain that implicitly informs URL features such as `suspicious_tld` and `num_subdomains`. This creates partial feature correlation across modalities that may inflate the apparent benefit of fusion—the model learns that combining two views of the same underlying signal (domain trustworthiness) is more predictive than either alone. A stricter experimental design would ensure strict modality independence by using disjoint information sources.

b) Temporal Data Snooping: Because the dataset is synthetic and all samples are generated simultaneously, there is no genuine temporal ordering to violate. However, in real-world deployment, evaluating a model trained on older phishing patterns against newer attacks introduces temporal distribution shift (concept drift). Our evaluation does not simulate this, potentially overestimating robustness to evolving attack strategies.

c) Hyperparameter Optimisation Bias: Default hyperparameters were used without cross-validated tuning. While this avoids overfitting, it means results may not represent the best achievable performance for each model, potentially underestimating the gap between classifiers that benefit more from tuning (e.g., XGBoost's learning rate).

B. External Validity

a) Evolving Phishing Techniques: Phishing tactics evolve rapidly. Features effective today (urgency vocabulary, newly registered domains) may become less discriminative as attackers adapt. The 2024 APWG report [1] notes a 36% year-over-year increase in phishing sites using HTTPS, eroding the discriminative power of `has_https`. Models require continuous retraining on fresh data to maintain performance.

b) Dataset Representativeness: Our synthetic dataset, while calibrated to known phishing patterns, does not capture the full diversity of real-world phishing campaigns—multilingual content, spear-phishing with personalised context, business email compromise (BEC) attacks using compromised legitimate accounts, and image-based phishing that evades text analysis entirely. Generalisation claims must be qualified accordingly.

c) Language and Cultural Bias: The TF-IDF vocabulary is English-only. Phishing campaigns increasingly target non-English speakers with localised content. A model trained on English urgency terms will have severely degraded text-modality performance on foreign-language emails, potentially biased toward over-classifying such emails as legitimate due to low urgency-term TF-IDF scores.

C. Construct Validity

a) Synthetic Data Distribution Assumptions: The decision to draw `domain_age_days` from $\mathcal{U}(1, 30)$ for phishing and $\mathcal{U}(365, 3650)$ for legitimate samples embeds a strong structural assumption: phishing always uses new domains and legitimate senders always use established ones. In practice, cloud services (AWS SES, SendGrid) use domains of varying ages, and some phishing campaigns use years-old compromised accounts, violating this assumption.

b) Synthetic Labels: All labels are programmatically assigned with zero noise. Real phishing datasets involve annotation ambiguity (borderline cases), label errors from automated classifiers used as ground truth, and temporal mislabelling when archived emails are reclassified as phishing post-hoc.

c) SHAP Independence Assumption: SHAP TreeExplainer uses path-dependent marginalisation that conditions on the training data distribution to handle feature correlations. However, TF-IDF features from related phishing vocabulary terms (e.g., `tfidf_verify` and `tfidf_confirm`) are positively correlated, and SHAP's attribution between them may not perfectly decompose joint effects, potentially inflating or deflating individual term importance.

VII. Ethical Considerations

The deployment of automated phishing detection systems raises substantive ethical concerns across six dimensions.

a) User Privacy in URL Analysis: Extracting structural URL metadata from email content requires parsing potentially sensitive URLs that may encode personal information (e.g., authentication tokens, account identifiers embedded in password-reset links). URL analysis pipelines must implement data minimisation—extracting only the structural features needed for classification without logging full URL strings that could expose user account states.

b) Consent for Email Content Analysis: Analysing email bodies via TF-IDF processes the private communications of users and senders without their explicit consent. Enterprise deployments must disclose email scanning practices in acceptable use policies. Regulatory frameworks including GDPR [29] (Article 6 legal bases for processing) and CCPA impose requirements on data controller notification and user rights to object to automated processing of personal communications.

c) False Positive Impact: Legitimate Emails Blocked: False positives—legitimate emails incorrectly quarantined as phishing—carry significant operational consequences. In enterprise environments, a quarantined invoice from a supplier or a client confirmation email can cause missed deadlines, revenue loss, and damaged business relationships. The system's probability outputs must be exposed with configurable thresholds so that security teams can tune precision-recall trade-offs based on operational risk tolerance. Blanket automated blocking without human review is inappropriate for borderline confidence scores.

d) Demographic and Linguistic Bias: Our model's text modality is trained on English urgency vocabulary. Applied to multilingual organisations, the text modality will systematically under-score non-English phishing emails (which lack English urgency terms), potentially creating differential detection rates across linguistic demographics. Conversely, the model may over-flag legitimate emails from non-English speaking contacts who use formal language patterns that incidentally overlap with phishing vocabulary in translated English. Fairness evaluations disaggregated by language and sender demographics are essential before enterprise deployment [30].

e) GDPR Data Processing Compliance: Processing email content for threat detection constitutes automated decision-making under GDPR Article 22 when phishing flags result in email delivery blocking without human review. Data subjects (both senders whose emails are scanned and recipients protected by the system) have rights to meaningful information about the logic of automated decisions. SHAP and LIME explanations generated by our framework directly support

GDPR transparency requirements by enabling human-readable explanations of individual email classifications. Data retention policies must be established for both email content and generated SHAP attributions, which themselves may encode sensitive information about email content.

f) Adversarial Phishing Evolution: Deploying and publicising this detection framework creates an arms-race incentive for adversaries to adapt. Knowing that temporal features dominate detection, sophisticated attackers can invest in aged domain infrastructure, use compromised legitimate accounts with long sending histories, and craft emails outside business hours using content with neutral vocabulary. Ethical deployment therefore requires: (1) withholding specific feature importance rankings from public disclosure; (2) implementing adversarial training augmentation; (3) maintaining human-in-the-loop review; and (4) participating in threat intelligence sharing to track emerging evasion tactics.

VIII. Data Availability Statement

The synthetic multi-modal phishing dataset, complete model training code, evaluation scripts, and SHAP/LIME explanation generation pipelines used in this study are available at https://github.com/x24260339/multimodal-phishing-detection (to be made public upon publication). The dataset is generated programmatically from documented distributional parameters; the generation script is included in the repository, enabling exact reconstruction of all 5,000 samples with `random_state=42`. No real user email data was used in this study. Figures and result CSV files are included in the repository's `outputs/` directory.

IX. Reproducibility Statement

Software. Python 3.10 with scikit-learn 1.3.2, XGBoost 2.0.3, LightGBM 4.1.0, SHAP 0.44.1, LIME 0.2.0.1, NumPy 1.26.0, pandas 2.1.0, matplotlib 3.8.0. A `requirements.txt` is included.

Hardware. Apple M2 (8 cores), 16 GB RAM, macOS 14. No GPU required. Total runtime: ≈12 minutes (LIME batch: ≈8 min).

Seeds. All RNGs seeded with `random_state=42` (NumPy, scikit-learn, XGBoost, LightGBM). Statistical tests across 10 seeds ($\{0, ..., 9\}$) are also included in the code for reproducibility.

X. Conclusion

This work presents a formally grounded, explainable multi-modal phishing detection framework combining text TF-IDF, URL structural, and temporal behavioural features via early feature-level fusion. Seven models are rigorously evaluated with full statistical validation (paired t-tests, McNemar's test, Cohen's $d = 4.33$, bootstrap CIs, Friedman test). Fusion-RF, Fusion-LGBM, and ProbFusion achieve perfect F1=1.000 on the synthetic test set, with the statistical advantage over the best single-modality baseline being significant ($p = 0.042$). A formal modality ablation identifies URL+Temporal as the most complementary pair, while text provides robustness under temporal feature unavailability. Cross-modal interaction analysis reveals that URL length combined with short domain age provides synergistic discriminative value exceeding either signal alone.

The dual-XAI consistency index ($J_{15} = 0.429$, Spearman $\rho = 0.933$) confirms substantial agreement between SHAP and LIME on feature rankings, with both methods independently identifying temporal features as dominant—a finding corroborated by the modality ablation. Error analysis reveals that the text-only baseline fails primarily on spear-phishing mimics with neutral language, a failure mode resolved by temporal signals. Comprehensive threats to validity and expanded ethics discussion (privacy, GDPR compliance, demographic bias, false positive impact, adversarial evolution) complete the framework for responsible deployment.

Future work will evaluate the framework on real-world phishing corpora (Nazario corpus, enterprise email logs), incorporate visual modalities (webpage screenshot embeddings), and explore attention-based cross-modal fusion for improved interpretability. Adversarial training and concept drift detection mechanisms will be essential components for production deployment.
